To the Editor,

With interest we read the article by Aydın et al. about “Clinical course of community-acquired respiratory syncytial virus (RSV) pneumonia in newborns hospitalized in neonatal intensive care unit” (1). We have the following comments and concerns.

The echocardiographic results of the patients were observed in this article. Secundum type atrial septal defect (ASD) has been noted in 7 patients. Four of them has been needed mechanical ventilation support. It has been noted that clinical course of RSV pneumonia was worse in patients with ASD. The authors also noted that ASD might negatively affect the course of the disease with increased viral load in lungs due to increased pulmonary blood flow.

RSV is a major cause of pneumonia in infants and young children worldwide (2-4). Pediatricians are using palivizumab prophylaxis in high risk infants to prevent RSV infection during RSV season. According to recommendations of American Academy of Pediatrics, congenital heart disease requiring palivizumab prophylaxis include cyanotic heart diseases, moderate to severe pulmonary hypertension and congestive heart failure requiring medication (5). In your study you think that ASD has been increased the disease severity due to increased pulmonary blood flow. We don’t agree your discussion. Because; during fetal life, the majority of the blood reaching the left atrium comes via foramen ovale. Since there is minimal flow to the lungs. After birth, the lungs expand and the pulmonary blood flow begins to increase. The increased pulmonary venous return to the left atrium results in the left atrial pressure exceeding the right atrial pressure causing functional closure of the foramen ovale. Intrauterine physiology is not altered in the presence of an ASD, but ASD does not close with hemodynamic changes that occur following birth. Also, during the neonatal period and infancy right and left ventricular wall thickness are the same. The left to right shunt is small.
in patients with ASD in this period. During the infancy and early childhood the right ventricular wall becomes thinner and hence more compliant than that of the left ventricle, there is an increase in left-to-right shunting. Thus, small ASDs result in trivial shunting and have no hemodynamic consequences. Larger defect are associated with substantial shunting, which may lead to volume overload of the right atrium, right ventricle and pulmonary arteries. Most patients with ASD are asymptomatic and may remain undiagnosed until later in life. Neonates or infants with ASD are not presented with features of pulmonary over circulation, recurrent respiratory infections and failure to thrive. Very rarely some neonates and infants may present with pulmonary over circulation. The mechanics of heart failure in these infants is not well understood since the hemodynamics are quite similar to those who are asymptomatic (6). Borow and Karp have proposed rapid remodeling and thinning of the pulmonary vascular bed to be the reason for this early presentation (7). For this reason pediatric cardiologists have not proposed the palivizumab prophylaxis in newborns and infants with ASD for prevention of RSV infection. We don’t agree that ASD may increase the disease severity in RSV pneumonia. We have never seen pulmonary over circulation in the neonates with ASD who were followed at our clinic.

There is a mis identification in Turkish abstract. “Bu oğullarda ASD daha ağır seyretmektedir” does not reflect the content of the article. It is not the same with each other in English and Turkish summary.
